1 Introduction and Motivation

1.1 Research Methodology

Methodology

1. Design Science process [**?**]
    1. problem identification and motivation
        1. specific research problem definition
        2. Value of a solution
        3. research state of the problem
    4. definition of objectives
        1. inferred from problem definition and knowledge of feasibility
    2. design and development
        1. creation of artifacts
        2. constructs, models, methods, instantiations
        3. determine artifacts desired functionality and architecture
    4. demonstration / evaluation
        1. demonstrate how artifact solves one or more instances of the problem
        2. compare actual artifact functionality with objectives
        3. perform surveys / gather client feedback
    4. communication

2 Workflow Management Systems

In this chapter, the concepts of workflows and workflow management systems will be briefly introduced and related to each other. There is a plethora of term definitions and deviating understandings of workflows and the concepts related to them [3]. In large parts, the concepts presented here thus rely on specifications published by the Workflow Management Coalition (WFMC), a consortium of workflow management software vendors, researchers in the field of workflow management and Workflow Management System (WfMS) users, as they represent some form of consensus.

The identified use cases and properties will be used in 4.1 to identify objectives for the architecture. Also, they will be the reference to which the final architecture developed in this thesis is compared against.

2.1 Concepts

2.1.1 Workflow

In order to achieve their business goals, organizations perform temporal and logical sequences of tasks that help to interact with business relevant entities. These sequences are known as *business processes*. If the logic that controls the processes is performed in an automated way, e.g. by an information system, one refers to the processes as *workflows* [2, 8]. The WFMC defines workflows as the computerized facilitation or automation of a business process, in whole or part [8].

Process activities are the atomic steps that processes consist of. The WFMC differentiates between *manual activities* and *workflow activities*. The former are activities that involve user interaction in order to be completed, while the latter are automated and require no interaction [8]. As the term "workflow activity" might be misunderstood as "any activity belonging to a workflow", in the following the term *automated activity* will be used instead.

2.1.2 Process Definition

In order to be able to execute workflows, the underlying business processes must be machine processable and thus have to be formalized from real world to an abstracted model [8]. This model is usually called *process definition* and stored in form of some high-level programming language construct [8, 13]. The process definitions typically consist of a collection of activities

with additional metadata such as associated applications or participants, and a set of rules which determine the execution order of these activities [8]. They further may contain references to other processes, which are treated as a single activity in the process definition [8, 3].

- usually directed grpah - how stored?

2.1.3 Process Instance

A *process instance* is an enactment of a process definition. A process definition may be instantiated multiple times, even at the same time. [3]. If only the automated parts of such an instance are meant, the WFMC advocates for the term *workflow instance* [8].

Process instances have several states. When they are created, they are in the *initiated* state. In this state, all relevant data has been provided, but the execution has not yet begun, e.g. because not all requirements are met. When the process is started, it enters the *running* state and it's activities may be started according to the process definition. If it has one or more instanciated activities, a process instance is in the *active* state. Process instances may be suspended, i.e. they enter the *suspended* state and no activities are instanciated until they leave it again. There are two states that a stopped process instance can be in. Either the completion requirements are met and the stopped process instance is in the *completed* state. Or the process instance stopped before its regular end, i.e. because of an error or manual interruption. In this case the process instance is in the *terminated* state [8].

A graphical representation of the state transitions described above can be seen in figure **??**. In this depiction, the allowed transitions between the different states are easy to grasp.

2.1.4 Activity Instance

Just like processes, activities are instanciated during workflow execution and have a set states that they may be in.

When an activity instance is created, it is in the *inactive* state. From this state, it may enter the *suspended* state, in which it will neither be activated nor assigned a worklist item. If the activity instance is not suspended, it is activated once its entry conditions are fulfilled. It then is in the *active* state. When the execution of the activity has finished, it finally enters the *completed* state [8].

The possible transitions between the activity instance's states can be seen in Figure **??**.

2.1.5 Workflow Data

In a WfMS, several forms of data may occur at diverse occasions. The WFMC differentiates between three types of data: workflow relevant data, workflow application data, and workflow control data [8].

WfMSs use *workflow relevant data* to determine a process instance's status and the next activity to be executed. It is normally available to the WfMS and both process- and activity instances [8].
Applications that are part of an workflow may work on domain specific data, which is called *workflow application data.* In most cases, the WfMS does not interact with this data other that providing it to the respective applications and limit access to it according to some authorization rules [8, 3].
Data that is internally managed by a WfMS is refered to as *workflow control data.* This data usually comprises the states of process- and activity instances and other internal statuses and is per se not interchanged in its default form [8, 3].

2.1.6 Workflow Participant and Worklist

There are workflows that contain activities which require user interaction. A WfMS thus provides the functionality to assign workflows and activities to workflow participants. This assignment can either be a specific one, targeting one single person, or be more general, targeting a set of users from which whe WfMS may choose during execution time. These sets are usually based on an organizational structure that manifests itself in roles, of which an user may have one or more [8, 3].

Each user has a so called *worklist* that consist of activities to which he is assigned to and which are scheduled for execution. Depending on the actual implementation, activites may appear on multiple users' worklists until one of them signals that he/she will work on it [8, 3].

2.2 Typical Architecture

With a growing number of workflows in an organization, the need arises to manage their creation, distribution and execution in a structured manner. An information system is called WfMS, if it is able to define, create and manage the execution of workflows by using software that runs on one or more workflow engines, is able to interpret process definitions, can interact with involved participants, and may invoke external applications [10]. According to the WFMC, a workflow management system is "a system that defines, manages and executes

workflows through the execution of software whose order of execution is driven by a computer representation of the workflow logic" [8].

In the following, the typical foundations of WfMSs architectures identified by the WFMC are presented and related to the concepts introduced in Section 2.1.

2.2.1 Functional Areas

The WFMC divides the reponsibilities of a WfMS in three functional areas: *build-time* functions, *run-time process control* functions and *run-time activity interaction* functions [8, 1].

The *build-time* functionalities are concerned with the abstraction of workflows, i.e. the creation of process definitions.
The *run-time process control* functionalities of a WfMS are dealing with instanciating and controlling processes, coordinating the execution of activities within a process instance, initiating (but not performing) both participant interaction and application invocation [8].
Some activites require users to enter data or applications to perform a specific task. The *run-time activity interaction* functions of a WfMS provide the possibilities to do so. They make forms available to users, instruct other applications, and collect the respective outcome [8].

2.2.2 System Components

The WFMC identified four software components that most WfMSs have in common: *Process Definition Tools*, *Administration and Monitoring Tools*, *Workflow Client Applications*, and *Workflow Enactment Service* [8].

Process Definition Tool

Process definition tools are responsible for analysis, modelling, description and documentation of business proceses. The output of process definition tools – process definitions – can be interpreted by workflow engines in order to enact the respective workflow.

The WFMC notes, that process definition tools do not necessarily have to be part of a WfMS, since the definition may take place in another tool as long as it is passed along in a standardized format [8].

Administration & Monitoring Tools

The administration and monitoring tools are responsible for high level monitoring and control of the system. Their functionalities may include user management, role management, logging, performance auditing, resource control, and supervision over running processes.

Workflow Client Applications

The core function of the workflow client applications is to let the user retrieve worklist items that were assigned to him/her. In the WFMC reference model they are thus sometimes referred to as *worklist handlers* [8].
Yet, the WFMC stresses that their functionality may be much broader, e.g. letting him/her enter data that is associated to one worklist item, allow him/her to alter the worklist, signing in or off, or control the processes' statuses. The WFMC thus advocates for the term *workflow client applications* [8]. The user interface may be part of the workflow client applications or exist as a separate software component.

Workflow Engine

Workflow engines provide the runtime control environment for the execution of workflow instances, that is, they interpret the process definition, manage the instances' status, update worklists, determine participants, and invoke external applications. They further manage the storage and flow of workflow control data and workflow relevant data [8].

Workflow Enactment Service

The Workflow Enactment Service groups one or more workflow engines into one logical component that exposes a single coherent external interface to other software [8].

2.2.3 WFMS Implementation Structure

According to the WFMC, the components described in 2.2.2 interlock in order to provide the overall functionality of a WfMS. As visible in **??**, the workflow enactment service plays a central role in wiring the components together.

3 Docker

When multiple applications or application instances shall be run on one physical machine without interfering with each other, they are usually isolated in terms of execution environments and provided with a controllable share of system resources [7]. These goals can be fulfilled by both virtual machines and software containers [12]. The difference between these two options and the basic principles of software containers are shown in 3.1.

Docker is a tool, that simplifies software container creation and management. In Section 3.1 its underlying concepts will be presented. Based on that, the functionality that Docker provides will be explained in Section **??**. Finally, the Docker ecosystem, i.e. the set of tools that enhance the core docker tool, is introduced in Section 3.3.

3.1 Concepts

First, the concept of software containers will be presented and contrasted against the concept of virtual machines. This is necessary to understand *what* Docker does. Then, internal constructs of Docker – images, containers, data volumes, dockerfiles, registries and repositories – are explained, in order to provide an understanding on *how* Docker does what it does.

3.1.1 Virtualization and Software Containers

The goal of *virtualization* is to simulate the presence of multiple computers on one machine. The use of this is XXX. There are two kinds of virtualization, one that takes place on the hardware level and another that takes place on the operating system (OS) level [12].

Hardware-level virtualization

In most cases when speaking about virtualization, *hardware-level virtualization* is referred to. It is usually driven by a *hypervisor* – a service that manages virtual machines and provides them with abstracted hardware devices to run on. This hypervisor either either runs in the OS of the host machine or directly on its hardware [12].
The virtual machines, i.e. the computers simulated on the host machine, require their own OS to be installed.

OS-level virtualization – or container-based virtualization

The other kind of virtualization, *OS-level virtualization,* is the one that Docker makes use of. It utilizes functions of the host kernel which allow the execution of several isolated userspace instances that share the same kernel, but may differ in terms of their runtime environment, e.g. file system or system libraries. These isolated userspace instances are usually called *software containers* or just *containers.* This type of virtualization is therefore also referred to as *container-based virtualization* [12].

The isolation and resource management in container-based virtualization on Linux systems are mainly achieved by two mechanisms, *control groups (cgroups)* and *namespaces.* While the former allows to group processes and manage their resource usage, the latter can be used on many system components. Namespaces may be introduced for example on network interfaces, the file system, users and user groups, process identifier (PID)s, and other components, in order to achieve a fine grained control over the respective isolation [12].
Besides Docker, there are several solutions that are all based on the aforementioned kernel features, e.g. LXC, LXD, lmctfy, systemd-nspawn, etc [12]. There are ongoing efforts to create a common container standard [9].

Many container solutions rely on a strategy called *copy-on-write (CoW)* to provide a runtime enviroment, which on the one hand lets the containers reuse system libraries and the like while on the other hand limits the container in affecting its surroundings [5, 11]. This strategy is explained in a more detailed fashion in 3.1.2 on the example of Docker.

3.1.2 Docker Images and Containers

CoW is a strategy which makes use of the benefits of both sharing files for read access and copying them to a local version previous to changing them. Processes that require access to a file share the same instance of that file. As soon as one process needs to alter the file, the operating system creates a copy to which only the process has access to. All other processes still use the original file [11, 5].

Docker images (referred to as just *images* from here) are the basis for Docker containers. Each image consists of a sequence of layers, where each layer summarizes one CoW step, i.e. the alterations to the file system that one command causes compared to the previous layer. Each layer is uniquely identifiable, which allows the same layer to be used by several images.

Docker containers are runtime instances of images. In the context of storage, a Docker container

can be considered as an image, i.e. a set of read-only layers, with a writable layer on top of it – the *container layer*. Write operations within a container trigger a CoW operation which copies the targeted file to the container layer, where the write operation is then performed.
Besides reducing the amount of space consumed by containers, the CoW strategy also reduces the time required to start a container. This is because Docker only has to create the container layer instead of providing a copy of all the filed contained in the respective image [5].

- *lifecycle of a docker container here*

3.1.3 Data Volumes

Any data written to the container layer is deleted as soon as its Docker container is deleted. Also, Docker containers that store a lot of data are considerably larger than Docker containers that do not, since the write operations require space in the container layer. This is the reason why data volumes exist – they are designed to persist data. Data volumes are directories or files that are mounted directly into a Docker container and thus bypass the storage driver [4]. They are never deleted automatically and therefore must be cleaned up manually when they are not needed anymore [5].

3.1.4 Dockerfiles

- text document that contains the commands one would normally execute manually in order to build a Docker image - Docker builds images automatically by reading the instructions from a Dockerfile [4]

3.1.5 Registries and Repositories

- registry: a hosted service containing repositories of images - repository: a set of Docker images [4]

3.2 Docker Engine

The Docker Engine forms the core of Docker. It features a daemon which provides the functionality and a command line interface (CLI) which controls said daemon [6]. Together, they enable the user to work with Docker containers.

3.3 Docker Ecosystem

3.3.1 Docker Swarm

3.3.2 Docker Machine

3.3.3 Docker Compose

3.3.4 Docker Hub

4 Application Design

4.1 Determination of Objectives

4.1.1 Functional Requirements

Infrastructure and Infrastructure Management
